Epidemiology of Osteoarthritis

Yuqing Zhang, DSc, *, Joanne M. Jordan, MD, MPH

Osteoarthritis (OA) is the most common joint disorder in the United States. Among adults 60 years of age or older the prevalence of symptomatic knee OA is approximately 10% in men and 13% in women. The number of people affected with symptomatic OA is likely to increase due to the aging of the population and the obesity epidemic.

Pain from OA is a key symptom in the decision to seek medical care and is an important antecedent to disability. Because of its high prevalence and the frequent disability that accompanies disease in major joints such as the knee and hip, OA accounts for more difficulty with climbing stairs and walking than any other disease. OA is also the most common reason for total hip and total knee replacement. The rapid increase in the prevalence of this already common disease suggests that OA will have a growing impact on health care and public health systems in the future.

DEFINING OSTEOARTHRITIS

Epidemiologic principles can be used to describe the distribution of OA in the population and to examine risk factors for its occurrence and progression. For the purpose of epidemiologic investigation, OA can be defined pathologically, radiographically, or clinically. Radiographic OA has long been considered the reference standard, and multiple ways to define radiographic disease have been devised. The most common method for radiographic definition is the Kellgren-Lawrence (K/L) radiographic grading scheme and atlas, which has been in use for over 4 decades. This overall joint scoring system grades OA in 5 levels from 0 to 4, defining OA by the presence of a definite osteophyte (Grade ≥ 2), and more severe grades by the presumed successive appearance of joint space narrowing, sclerosis, cysts, and deformity. Other radiographic metrics including semiquantitative examination of individual radiographic features, such as osteophytes and joint space narrowing, or the direct measurement...
of the interbone distance as an indicator of the joint space width in the knees and hips, are used to investigate progression in epidemiologic studies and clinical trials of disease-modifying therapies. More sensitive imaging methods using magnetic resonance imaging (MRI) can visualize multiple structures in a joint and are undergoing evaluation for their role in defining OA and for their usefulness in detecting the effects of potential disease-modifying interventions more quickly than is possible with conventional radiographs.

Studies of OA in people who have joint symptoms may be more clinically relevant, because not all persons who have radiographic OA have clinical disease, and not all persons who have joint symptoms demonstrate radiographic OA. Each set of clinical and radiographic criteria may yield slightly different groups of subjects defined as having OA.

PREVALENCE AND INCIDENCE OF OSTEOARTHRITIS

The prevalence of OA varies according to the definition of OA, the specific joint(s) under study, and the characteristics of the study population. The age-standardized prevalence of radiographic knee OA in adults age 45 years or older was 19.2% among the participants in the Framingham Study and 27.8% in the Johnston County Osteoarthritis Project. In the third National Health and Nutrition Examination Survey (NHANES III), approximately 37% of participants older than 60 years had radiographic knee OA.

Age-standardized prevalence of radiographic hand OA was 27.2% among the Framingham participants. Radiographic hip OA was less common than hand or knee OA. For example, about 7% of women age 65 years or older in the Study of Osteoporotic Fractures had radiographic hip OA. However, prevalence of hip OA was much higher in Johnston County, with 27% of subjects at least 45 years old demonstrating radiographic evidence of K/L grade 2 or higher OA. Potential explanations for the differences between these studies relate to differences in study populations, definitions of OA, distribution of risk factors for disease, and radiographic readers.

Symptomatic OA is generally defined by the presence of pain, aching, or stiffness in a joint with radiographic OA. The age-standardized prevalence of symptomatic hand and knee OA is 6.8% and 4.9%, respectively, in Framingham subjects age 26 years or older. However, prevalence of symptomatic knee OA was 16.7% among subjects age 45 or older in the Johnston County Osteoarthritis Project, much higher than that reported in the Framingham Study. About 9% of subjects in the Johnston County study had symptomatic hip OA. There is a paucity of meaningful data on the cumulative incidence of developing OA. Here, the length of time over which the risk of OA is calculated is critical but is not always clearly specified or known. Further, because OA is a chronic disease occurring mostly among the elderly, competing risk or death from other diseases makes direct estimation of the cumulative incidence of OA difficult.

Oliveria and colleagues reported the age- and sex-standardized incidence rates of symptomatic hip, knee, and hand OA to be 88, 240, and 100 per 100,000 person-years, respectively, in participants in a Massachusetts health maintenance organization, and the incidence rates of symptomatic OA of either hand or knee, or hip increased rapidly around age 50 and then leveled off after age 70 (Fig. 1). Murphy and colleagues estimated the lifetime risk of developing symptomatic knee OA to be about 40% in men and 47% in women. Such a risk rises to 60% in subjects with body mass index (BMI; calculated as the weight in kilograms divided by height in meters squared) of 30 or higher.
RISK FACTORS FOR OSTEOARTHRITIS

OA has a multifactorial etiology, and can be considered the product of an interplay between systemic and local factors as shown in Fig. 2.1 For example, a person may have an inherited predisposition to develop OA but may only develop it if an insult to the joint has occurred. The relative importance of risk factors may vary for different joints, for different stages of the disease, for the development as opposed to the progression of disease, and for radiographic versus symptomatic disease. There is even some evidence suggesting that risk factors may act differently according to individual radiographic features, such as osteophytes and joint space narrowing.1 Whether some of these differences are genuine or are spurious results of different study populations, definition of risk factors and OA, statistical power, or analytical methods is open to debate.

SYSTEMIC RISK FACTORS FOR OSTEOARTHRITIS

Age

Age is one of the strongest risk factors for OA of all joints.1,6,15 The increase in the prevalence and incidence of OA with age probably is a consequence of cumulative exposure to various risk factors and biologic changes that occur with aging that may make a joint less able to cope with adversity, such as cartilage thinning, weak muscle strength, poor proprioception, and oxidative damage.

Gender and Hormones

Women not only are more likely to have OA than men, they also have more severe OA.16 The definite increase in OA in women around the time of menopause has led
investigations to hypothesize that hormonal factors may play a role in the development of OA. However, results on effect of estrogen, either endogenous or exogenous, on OA from observational studies have been conflicting.\textsuperscript{17–19} In a randomized clinical trial (the Heart and Estrogen/Progestin Replacement Study) in a group of older postmenopausal women with heart disease, no significant difference was found in the prevalence of knee pain or its associated disability between those taking estrogen plus progestin therapy or those taking placebo.\textsuperscript{20} Data from the Women’s Health Initiative showed that women on estrogen replacement therapy were 15\% less likely to require total knee or hip arthroplasty than those not taking such therapy (hazard ratio 0.86; 95\% confidence interval 0.70–1.00), but that estrogen combined with progestin therapy was not associated with the risk of joint replacement.\textsuperscript{21}

**Race/Ethnicity**

The prevalence of OA and patterns of joints affected by OA vary among racial and ethnic groups. Both hip and hand OA were much less frequent among Chinese in the Beijing Osteoarthritis Study than in whites in the Framingham Study,\textsuperscript{22,23} but Chinese women in the Beijing Osteoarthritis Study had significantly higher prevalence of both radiographic and symptomatic knee OA than white women in the Framingham Study.\textsuperscript{24} Results from the Johnston County Osteoarthritis Project have shown that the prevalence of hip OA in African American women (23\%) was similar to that in white women (22\%), and prevalence was slightly higher in African American men (21\%) than that in white men (17\%).\textsuperscript{25} It is of interest that prevalence of individual radiographic features of hip OA varied between African Americans compared with whites. For example, superior joint space narrowing and osteophytes at lateral compartment are more common in African Americans than in whites.\textsuperscript{25} In addition, African Americans were also more likely to have more severe and tricompartmental osteophytes than their white counterparts.\textsuperscript{26} Whether some of these racial/ethnic differences are related to differences in anatomic femoral and acetabular features, shown to be important in radiographic hip OA in whites,\textsuperscript{27,28} is worthy of further study.
Genetics

Results from several studies have shown that OA is inherited and may vary by joint site. Twin and family studies have estimated the heritable component of OA to be between 50% and 65% with larger genetic influences for hand and hip OA than for knee OA. In a genome-wide association study, Kerkhof and colleagues reported that the C allele of rs3815148 on chromosome 7q22 was associated with a 1.14-fold increased prevalence of knee and/or hand OA and also with a 30% increased risk of knee OA progression. Several studies also found that an inverse association between general joint hypermobility, a lone benign trait, with hand and knee OA and serum cartilage oligometric matrix protein levels.

Congenital/Developmental Conditions

A few congenital or developmental abnormalities (ie, congenital subluxation, Legg-Calvé-Perthes disease, and slipped capital femoral epiphysis) have been associated with occurrence of hip OA in later life; however, because these developmental deformities are uncommon, they probably only account for a small proportion of the hip OA in the general population. Several studies have examined subclinical acetabular dysplasia, a more common, milder developmental abnormality, in relation to hip OA, with conflicting results. Lane and colleagues reported that abnormal center-edge angle or acetabular dysplasia were each associated with an approximately three-fold increased risk of incident hip OA in women, suggesting that subclinical acetabular dysplasia may be a significant risk factor for the development of hip OA.

Diet

Dietary factors are the subject of considerable interest in OA; results of studies, however, are conflicting. One of the most promising nutritional factors for OA is vitamin D. Without sufficient vitamin D, bones can become thin, brittle, or missshapen. In the Framingham Study subjects in the lowest (≤27 ng/mL) and middle (27.0–33.0 ng/mL) tertile of serum 25-hydroxyvitamin D had a threefold increased risk for progressive knee OA compared with those in the highest tertile; however, no such effect was observed for risk of incident disease. In the Study of Osteoporotic Fractures, women in the middle (23–29 ng/mL) and lowest (8–22 ng/mL) tertiles of serum 25-vitamin D were 3 times as likely to develop incident hip OA, defined by joint space narrowing, as those in the highest tertile (30–72 ng/mL). However, serum vitamin D levels were not associated with the risk of hip OA characterized by osteophytes or with new disease defined according to the summary grade. However, results from 2 cohort studies failed to confirm any protective effect of vitamin D on the structural worsening of knee OA. A randomized, placebo-controlled clinical trial of vitamin D is currently underway to examine whether this vitamin can affect knee symptoms and cartilage loss measured on MRI in established knee OA.

Low vitamin C dietary intake was associated with an increased risk of progression, but not incidence, of both radiographic and symptomatic knee OA among the participants in the Framingham Study. In the Johnston County Osteoarthritis Project subjects with a high ratio of α:γ tocopherol had 50% lower risk in development of radiographic knee OA. However, results from a controlled clinical trial of vitamin E failed to ameliorate symptoms in patients who had symptomatic knee OA or to prevent knee OA progression, as measured by cartilage volume by MRI.

Animal studies have shown that selenium deficiency is associated with irregular bone formation, decreased bone strength, and abnormalities in type I and II collage in cartilage. Animal studies have also been performed in animals where selenium levels are low, with findings suggesting that selenium is important for bone health and cartilage integrity. In areas of China and eastern Asian where selenium levels in the food supply are low, populations have been found to have higher rates of OA than in regions with adequate selenium intake.
soil are extremely low, the prevalence of Kashin-Beck disease, an early onset of osteoarthropathy, was also high and food supplementation with selenium decreased the incidence of this disease.\(^{50,51}\) Preliminary results from the Johnston County Osteoarthritis Project have shown that suboptimal selenium levels, measured in toenails, were associated with worse knee OA.\(^{52}\) However, others have reported that high selenium intake was significantly associated with increased risk of both hip and knee OA.\(^{53}\)

In one study, high levels of serum vitamin K were associated with a low prevalence of radiographic hand OA, particularly for the presence of large osteophytes.\(^{54}\) The relation of serum vitamin K levels to knee radiographic OA is less clear. A recent randomized, placebo-controlled trial of vitamin K supplementation (phylloquinone, 500 \(\mu\)g/d) did not confirm a protective effect of vitamin K on the severity of radiographic hand OA.

**LOCAL RISK FACTORS**

**Obesity**

Obesity and overweight have long been recognized as potent risk factors for OA, especially OA of the knee.\(^1\) The results from the Framingham Study demonstrated that women who had lost about 5 kg had a 50\% reduction in the risk of development of symptomatic knee OA.\(^{55}\) The same study also found that weight loss was strongly associated with a reduced risk of development of radiographic knee OA. Weight-loss interventions have been shown to decrease pain and disability in established knee OA.\(^{56,57}\) The Arthritis, Diet, and Activity Promotion Trial showed that weight loss combined with exercise, but neither weight loss nor exercise alone, were effective in decreasing pain and improving function in obese elders who had symptomatic knee OA.\(^{56}\) Results from a meta-analysis concluded that although the effects of weight loss on pain were less consistent, weight reduction by about 5\% was associated with an improvement of physical function.\(^{57}\)

The relationship between overweight and hip OA is inconsistent and, if it exists, is weaker than that with knee OA.\(^{58,59}\) There is, however, more consistent evidence that obesity increases the risk of bilateral radiographic as well as symptomatic hip OA.\(^{60}\) In the Nurses’ Health Study, higher BMI, especially BMI at age 18, was strongly associated with an increased risk of total hip replacement therapy.\(^{61}\) Increased loading on the joint is probably the main, but not only, mechanism by which obesity causes knee or hip OA. Overloading the knee and hip joints could lead to synovial joint breakdown and failure of ligamentous and other structural support.

**Injury/Surgery**

Numerous studies have shown that knee injury is one of the strongest risk factors for OA. Severe injury to the structures of a joint, particularly a transarticular fracture, meniscal tear requiring meniscectomy, or anterior cruciate ligament injury, can result in an increased risk of OA development and musculoskeletal symptomatology.\(^{62,63}\) In the Framingham Study the prevalence of meniscal damage was much higher among subjects with radiographic knee OA (82\%) than those without OA (25\%). The prevalence of meniscal damage increased with an increase in K/L grade \((P<.001\) for trend); among those with moderate (K/L = 3) and severe (K/L = 4) radiographic knee OA, 95\% had evidence of meniscal damage.\(^{64}\)

**OCCUPATION**

Repetitive use of joints at work is associated with an increased risk of OA. Studies have found that farmers have a high prevalence of hip OA.\(^{65}\) The prevalence of
Heberden nodes was much higher in cotton mill workers, whereas spinal OA was no more common in these workers than in controls.\textsuperscript{66} Workers whose jobs required repeated pincer grip had more OA at distal interphalangeal joints than did workers whose job required power grip.\textsuperscript{67}

The risk of development of knee OA was more than 2 times greater for men whose jobs required both carrying and kneeling or squatting in mid-life than for those whose jobs did not require these physical activities.\textsuperscript{68} The risks of knee OA associated with kneeling and squatting were much higher among subjects who were overweight or whose job also involved lifting.\textsuperscript{69}

**Physical Activity/Sports**

Studies examining the relationship between sports activities and subsequent OA have produced conflicting results. There is some evidence that elite long-distance runners are at high risk for the development of knee and hip OA,\textsuperscript{70–72} and that elite soccer players are at higher risk of getting knee OA compared with athletes who do not play soccer.\textsuperscript{71,73} Surprisingly, the general level of physical activity itself may also increase the risk of OA. For instance, physical activity among elderly subjects in the Framingham Study was generally characterized by leisure-time walking and gardening. However, persons who engaged in relatively high levels of such activity had a threefold greater risk of developing radiographic knee OA than sedentary persons over 8 years of follow-up.\textsuperscript{74} Similar findings were reported in another study in which women who had a high lifetime level of physical activity had a high prevalence of hip OA.\textsuperscript{75} By contrast, others have shown that, in the absence of acute injury, recreational (moderate) long-distance running and jogging did not appear to increase the risk of OA.\textsuperscript{76,77}

**Mechanical Factors**

The relationship between muscle strength and OA is complex, may vary by joint site, and is not entirely understood. Muscle weakness and atrophy commonly associated with knee OA had been thought to be the product of disuse resulting from pain avoidance. One study reported that women who had asymptomatic radiographic knee OA but had no muscle atrophy showed quadriceps muscle weakness,\textsuperscript{78} suggesting that this might be a risk factor for the development of symptomatic knee OA.\textsuperscript{78} Baker and colleagues\textsuperscript{79} confirmed that persons who had both asymptomatic patellofemoral and tibiofemoral radiographic knee OA had weaker quadriceps strength than those who did not have OA.\textsuperscript{79} In a follow-up study quadriceps muscle weakness not only resulted from painful knee OA but also increased the risk of knee structural damage.\textsuperscript{80,81} Other studies,\textsuperscript{82} however, showed that greater quadriceps muscle strength in the setting of malalignment and laxity may actually be associated with an increased risk of knee OA progression.

Using the data from the Genetics of Generalized Osteoarthritis Study, Dominick and colleagues\textsuperscript{83} found an inverse cross-sectional association between grip strength and OA of the carpometacarpal joint and between pinch strength and OA of the metacarpophalangeal joint. On the other hand, greater grip strength was associated with an increased risk of radiographic hand OA among the participants of the Framingham Study: men whose maximal grip strength was in the highest tertile had a threefold increased risk of OA in the proximal interphalangeal, metacarpophalangeal, or thumb base joints, as compared with those with lowest tertile.\textsuperscript{84} The investigators suggested that the maximal force exerted on specific joints might influence development of OA in those joints.

**Alignment**

Knee alignment (ie, the hip-knee-ankle angle) is a key determinant of load distribution. Any shift from a neutral or collinear alignment of the hip, knee, and ankle affects load
distribution at the knee. Therefore, one would speculate that malaligned knees may have a higher risk of developing OA and a higher subsequent risk of progression than knees with neutral alignment.

In a prospective cohort study, Sharma and colleagues demonstrated that in the presence of existing knee OA, abnormal anatomic alignment was strongly associated with accelerated structural deterioration in the compartment under greatest compressive stress. Knees with varus alignment at baseline had a fourfold increase in the risk of medial progression of knee OA, and those with valgus alignment at baseline had a nearly fivefold increase in the risk of lateral progression. The same study also found that the impact of varus or valgus malalignment on the risk of OA progression was greater in knees with more severe baseline radiographic disease than knees with mild or moderate disease. Another study found that knee malalignment was associated with the size and progression of bone marrow lesions as well as with rapid cartilage loss on MRI.

The association between malalignment and risk of incident knee OA is less clear, however. The results from the Rotterdam study found that among knees with K/L grade 0 and 1, knees with valgus alignment had a 54% increased risk and knees with varus alignment had a twofold increased risk for the development of radiographic knee OA, compared with normal aligned knees. In the Framingham Study, however, Hunter and colleagues, using 4 measures of knee joint alignment (ie, the anatomic axis, the condylar angle, the tibial plateau angle, and the condylar tibial plateau angle), found none of these measures to be associated with an increased risk of incident radiographic knee OA. The investigators speculated that malalignment may not be a primary risk factor for the occurrence of radiographic knee OA but rather a marker of disease severity and/or its progression.

Laxity

Knee laxity is another potential risk factor for knee OA. Varus-valgus knee laxity is greater in the nonarthritic knees of patients who have idiopathic disease than in the knees of controls, suggesting that a portion of the increased laxity of knee OA precedes disease development and may predispose to disease. Moreover, sagittal plane or anterior-posterior laxity may be increased in persons who have mild OA, and anterior-posterior laxity seems to decline with increasing severity of knee OA. Because knee laxity may be altered by the disease itself, longitudinal data will be helpful in confirming these relationships.

Another factor that can alter biomechanics at the knee and hip is limb length inequality (LLI). In the Johnston County Osteoarthritis Project persons with an LLI of at least 2 cm were almost twice as likely to have radiographic knee OA and 40% more likely to have knee symptoms. The results from the Multicenter Osteoarthritis Study also demonstrated that leg length inequality of 1 cm or more was not only associated with a higher prevalence of prevalent radiographic knee OA but also increased the risk of incident symptomatic and progressive knee OA. These results point to LLI as a potentially modifiable risk factor for knee OA.

RISK FACTORS FOR SYMPTOMATIC OSTEOARTHRITIS

Although symptomatic knee OA is common, causes substantial disability, and consumes tremendous medical costs, most previous studies have focused on risk factors for radiographic OA. Not all risk factors for radiographic OA are strong predictors of joint symptoms. Women with radiographic knee OA were more likely to have symptoms than men, and African Americans generally reported more knee and hip
symptoms than whites. Strenuous physical activity, especially activities requiring kneeling, knee-bending, squatting, and prolonged standing, as well as knee injury and trauma, have also been linked to a high prevalence of symptomatic knee OA. People who have severe radiographic OA are more likely to report joint pain than those with milder radiographic abnormalities. Results from 2 observational studies have demonstrated that there was a strong dose-response relation of the severity of radiographic knee OA to the prevalence of frequent knee pain, consistent frequent knee pain, and pain severity. Furthermore, joint space narrowing was more strongly associated with each pain measure than were osteophytes.

A few studies have demonstrated that several morphologic and pathologic changes detected by MRI, namely bone marrow lesions, synovitis, effusion, or periarticular lesions in the knee, were associated with knee pain, but others have failed to confirm the association between bone marrow lesions and knee pain.

Studying risk factors for symptomatic OA is challenging. While pain in OA has long been considered chronic, it is not necessarily constant. Physicians often notice that clinically, patients with OA experience episodes of recurrent pain or pain exacerbation over the course of the disease. The pain from OA often worsens by using the involved joints, and lessens or is relieved with rest. Such pain patterns are also observed in epidemiologic studies. Gooberman-Hill and colleagues reported that joint pain among subjects with knee or hip OA is often intermittent and variable, and adaptation and avoidance strategies modify the experience of pain. Because of methodological and logistical difficulties, however, few studies have been conducted to examine the dynamic relationship between risk factors and pain fluctuation. One such study used weekly telephone interviews over 12 weeks to assess the impact of fluctuations in knee or hip pain. Fluctuations were frequent and were observed in about 49% of individuals, and decreases in pain were associated with improved function, decreased work absenteeism, sleep disruption, and health care resource use.

SUMMARY

Evolving definitions of OA and improvement in risk factor measurement, by using advanced imaging, systemic and local biomarkers, and improved methods for measuring symptoms and their impact, can help to elucidate mechanisms and identify potential areas for intervention or prevention. The application of these new sources of knowledge about the OA process holds promise for the development of new, potentially disease-modifying pharmaceuticals and nonpharmacologic therapies.
