24.1 INTRODUCTION

Modern societies understand the world, manifest different viewpoints, and test their objectiveness by exchanging information through direct communication or, in more recent years, through online social networks. On a larger scale, this process may also create consensus and mitigate social friction through public debate, two essential aspects of a healthy democracy. Information diffusion is often represented by pieces of information (e.g., news, scientific, or historical facts) that spread through a network. As for the network, that consists of interacting entities such as individuals, institutions (e.g., governments, authorities, or other organizations), and private entities (e.g., media, marketing agencies).

The Internet era has offered new means to produce and share information through large-scale online social networks. The disposition of large amounts of data coming from diffusion traces has helped scientific research improve our understanding of diffusion processes arising in various disciplines, including sociology, epidemiology, marketing, and computer system security. However, the democratization of content creation and sharing has not been adequately coupled with effective (self-, collective, or automatic) moderation, correction, and filtering mechanisms. Consequently, the explosive volume of the available content brings forward huge challenges regarding the human capacity to process that fast-paced and gigantic information stream as well as regarding the technical aspects of data management.

Our daily information diet tends to promote the variety in the content we consume to the expense of its precision and detail. During moments of crisis, the scarcity of trustworthy information and lack of time to analyze it lead to the proliferation of false rumors. There are also various psychological factors that impact the way we participate in this exchange. For instance, people get influenced by others, but also tend to search and recall information and facts that align with their already formed belief system (confirmation bias).

Furthermore, users interact preferably with people of similar profiles and opinions (homophily), a tendency that greatly reduces the heterogeneity of the user’s perceived public debate. In addition, members of any online group receive social pressure to conform to a group’s beliefs; that tends to
radicalize opinions and allow questionable ideas to gain momentum (*echo chambers*). Then, the relative isolation of small online communities may lead them to believe in false rumors, even create a false consensus against what is considered as verifiable by the majority of society. The situation may get considerably aggravated in periods of political tension where polarization and partisanship grow in well-segregated groups that reduce significantly their exposure to counterarguments.

**Rumor spreading and control.** There are many types of misinformation: bad or “yellow” journalism, fake news, rumors and unverified information, hoaxes, and others (for a discussion on the taxonomy see [1]). Despite the fact that many studies hardly distinguish these types, there are still notable differences with regards to the *actors* propagating unverified or untrue information (e.g., individuals, media, politicians, or authorities), their *motives* (e.g., ignorance, desire to be part of a movement, gaining visibility and revenues, or as part of a speculative communication campaign), and the way people interact with a new piece of information in each of those cases, especially during its verification process. As has been pointed out, terms such as “fake news” are just new names for very old problems. The particular recent concern of public opinion on fake news is, however, due to the fact that the cascading effects of misinformation gain magnitude and speed in online social networks, and thus their short-term negative impact is boosted. These effects have been recorded in numerous major events, such as terrorist attacks, social demonstrations, elections, natural disasters, and wars.

In this chapter we mainly refer to *untrue rumors* that represent false information and may have malicious motives. Such rumors are usually proven false shortly after their appearance. However, the debunking may not propagate fast enough in the social network to prevent a rumor from pursuing its diffusion (this is also the case, for example, of long-lasting rumors such as conspiracy theories) and that is exactly the point where computational tools can be beneficial.

There have been many developments in recent decades concerning both information dissemination and viral epidemics on networks. Despite the particular properties of rumor spreading, it is still a type of information diffusion for which many generic models and results are therefore relevant. Early models originated from the Susceptible-Infected-Removed (SIR) epidemic model [2,3] and a detailed related work is provided in the next section. Worth mentioning though, is the modern family of Information Cascade Models (ICMs) [4], which considers heterogeneous node-to-node transmission probabilities. ICM fits well to problems related to information diffusion on social networks and, among others, finds straightforward applications in digital marketing [5]. Indeed, ICMs were used to fit real information cascade data and observed node “infection” times in the MemeTracker dataset [6]. In another work, the aim was to infer the edges of a diffusion network and estimate the transmission rates of each edge that best fit the observed data [7].

Theoretical studies have given valuable insights on diffusion processes by defining quantities tightly related with the systemic behavior (e.g., epidemic threshold, extinction time) and describing how a diffusion unfolds from an initial set of contagious nodes. Most notably, a number of studies highlighted the crucial role that the network structure plays in how the diffusion process unfolds, which is also the

---

1 According to the Oxford English Dictionary, a rumor is “a currently circulating story or report of uncertain or doubtful truth.” Thus, a rumor is by definition uncertain and may eventually be true or false. However, what will always be problematic is the fact that rumors gain disproportional circulation speeds to their level of certainty.
subject on which this chapter is largely devoted. The relation between the network structure and the behavior of SIR epidemics has been shown in [8]. Follow-up works verified this relation and broadened the discussion to other types of diffusion models [9,10]. Similar theoretical results have then been given for ICM as well [11,12].

The quantification of systemic properties can help on the direction of risk assessment (e.g., economic, health, social risks) and, furthermore, enable diffusion process engineering whose aim could be either to suppress or enhance a spreading. Under ICM, this engineering task is also named in literature as influence optimization or activity shaping, whereas the maximization has received a lot of attention for its direct marketing applications. In recent years, the suppression of information diffusion processes has also become a hot topic because it is related to various security hazards, e.g., due to cascades of misinformation such as harmful rumors and fake news. Suppressive scenarios of the latter type are also possible in the ICM modeling context; the optimization problem would be the minimization of the spread of a piece of information in the network, e.g., by decreasing the probability for certain users to share the false content to their contacts. To the best of our knowledge there is no prior work on this direction and part of the contribution of this chapter is exactly on covering this gap by developing computational approaches that are able to reduce an undesired spread under the ICM.

**Contribution and summary.** The rest of the chapter keeps its focus on information diffusion and is structured as follows. We commence with the detailed related work (Section 24.2), the technical background regarding diffusion models (Section 24.3), and their dynamics as stochastic processes (Section 24.4). The reader may find helpful the Table 24.1 which lists the main notations we use in this chapter. Then, we discuss one of the interesting tasks arising in diffusion networks: the offline influence optimization through local intervention actions that affect the information spread (Section 24.5). The purpose can be either to minimize or maximize the influence by means of suppressive or enhancive actions, respectively. An efficient strategy should decide where on the network to perform a number of available actions (limited by a budget of resources) in order to better serve one of those two opposing aims.

To this end we extend the discussion with the novel approach that first appeared in [13], which frames this task as a generalized optimization problem under the ICM and enjoys a convex continuous relaxation. In particular, we present a class of algorithms based on the optimization of the spectral radius of the Hazard matrix using a projected subgradient method (Section 24.6). For these algorithms, which can address both the maximization and the minimization problem, we provide theoretical analysis. The suppressive case is, however, more interesting in the context of this chapter as it is straightforwardly related to the control of undesired diffusion processes such as the spread of rumors. Hence, we investigate two standard case-studies of the minimization problem (Section 24.7): the quarantine (e.g., see [10,14]) and the node immunization problem (see [15]).

Notably, among the major strengths of this framework is the fact that it can describe complex strategies that are able to use several immunization options by deploying simultaneously resources of different types (partial or total immunization of edges and nodes, etc.). We also discuss how such strategies could find practical application to rumor control scenarios. In a section with experimental results (Section 24.8), the main presented control algorithm, called NetShape, is compared to standard baselines and state-of-the-art competitors in synthetic and benchmark network datasets. In the last section (Section 24.9), we give our conclusions and directions of future research.
24.2 RELATED WORK

**Modeling information and rumor spreading.** Phenomena such as rumors are part of an old story that is adapted to the current technological context. Scientists started studying rumors and stories related to the two World Wars. Knapp [2], and soon after Allport and Postman [3,16], were among the first to analyze rumors and pose the question of their control. In the work of the latter two, it was pointed out that, loosely speaking, the spread of rumors is somewhat proportional to the general interest of the story and the ambiguity of the related evidence. The similarities between rumor and disease spreading were also noted in later literature, though Daley and Kendal were the first to connect epidemics and rumors in mathematical terms [17,18]. However, they noted that their dynamics may be strikingly different due to the particularly complex rumor-spreading mechanism. Specifically, they introduced a variant of the Susceptible-Infected-Removed (SIR) epidemic model, where stochastic recoveries are triggered either when (a) an infected node interacts with an already recovered one, or (b) two infected nodes interact and both may then recover. A slight modification was proposed in [19] concerning case (b) where only the infected node that initiates the interaction may recover.

These alterations to the basic epidemic model try to incorporate mechanisms where a person is probable to lose motivation in continuing to spread a rumor when he realizes that it is no longer novel and interesting, or has already been debunked. Interesting to note, though, there is no assumed self-recovery process and the recovery is rather brought about by crowdsourcing. This is in accordance to follow-up and recent data-driven studies on rumor spreading on Twitter, which from one side observed self-correction to be very weak and slow to take effect while from the other side they observed an almost 1:1 ratio of users promoting important false rumors and users trying to debunk them [20,21].

Over the course of years, more refined SIR-like epidemic models were proposed for information diffusion, including rumors, that still have a permanent recovered state (for a survey on compartmental models see [22,23]). One example is the SEIR model that introduces the (E)xposed state in which the individual is infected but incubating before getting to (I) and become infectious to others. Another example is SEI[R]Z [24,25] that introduces competition among adopters at state (I) and those at state (Z) who, after infection, have become skeptics. Both adopters and skeptics recruit from the susceptible population; nodes can “exit” the system and change the population size over time. However, the state (S) also recruits from a general population that is out of the system, and one could assume that previously departed individuals may later become susceptible again.

Evidently, the most popular epidemic modeling choice for information cascades, including rumors, are the **monotonically increasing stochastic models** such as SIR that allow node transitions only toward more critical states and eventually lead to permanent recovery or removal (i.e., as if the node dies out). Indeed, such modeling fits to what is observed in high-frequency information circulation with a short life, a setting that covers the majority of the content reaching users from social networks, news broadcasts, the entertainment industry, and advertising. Nevertheless, for an information spread that spans longer time periods and may come and go in current affairs (e.g., political issues, ideas, competing products, long-lasting rumors), models that allow reinfection are definitely more relevant. In this sense, the Susceptible-Infected-Susceptible (SIS), or the more information-oriented SEI[R]Z [24,25], could be fit better and also enable dynamic approaches for suppressing a diffusion, e.g., the **priority-planning** [26] or the greedy approach of [27].

More recently, Information Cascade Models (ICMs) were introduced that have higher detail and can take advantage of the wealth of available social interaction data to fine-tune their parameters.
First, independent cascades have emerged as a relevant model for viral diffusion of ideas and opinions [7,28–30]. Similarly to SIR, independent cascades are also increasing stochastic processes. However, contrary to epidemic models, they capture the precise temporal dependencies between infection events of neighboring nodes but require larger training datasets to infer them properly. Second, multivariate Hawkes processes are self-exciting point processes that are considered the gold standard to deal with sequences of correlated events in many scientific fields, e.g., for earthquake prediction [31] as well as in biological [32], financial [33,34], and social interactions studies [35]. They were thus naturally adapted to information diffusion in social networks with the main advantage of allowing multiple events on a single node (e.g., posts, likes, or shares in the case of a social network) [36,37]. Finally, Linear Threshold Models were developed to account for more complex diffusion dynamics in which users may require more than one concordant piece of information to accept it [28].

**Influence optimization.** The first attempts to put forward computational approaches for assessing the influence of users in social networks were those in [38,39]. The *influence maximization* problem under the ICM was first formulated in [5]. It was proved that it is an NP-hard problem and remains NP-hard to approximate it within a factor \(1 - 1/e\). It was also proven that the influence is a submodular function of the set of initially contagious nodes (referred to as *influencers*) and the authors proposed a greedy Monte Carlo-based algorithm as an approximation. A number of subsequent studies were focused on improving that technique [40,41]. Notably, today’s state-of-the-art techniques on influence control under the ICM are still based on Monte Carlo simulations and a greedy mechanism to select the actions sequentially.

Besides the popularity of influence maximization, various questions regarding how one could apply suppressive interventions have also become a hot topic in recent years. However, to the best of our knowledge, there is no existing work under the ICM and, as mentioned in the introduction, the methodological contribution of this chapter is on the development of computational approaches under the ICM that are able to efficiently reduce an undesired spread (see Section 24.5).

**Network structure, information spread, and control approaches.** Recent theoretical studies have highlighted how crucial the structure of the underlying network is for the behavior of a diffusion process. Specifically, they have studied the way structural characteristics of the network do appear in quantities that are tightly related with the process behavior, such as the epidemic threshold and the extinction time.

An early work that drew a line between epidemic spreading and the structural properties of the underlying network is that in [8]. Under a mean field approximation of an SIR epidemic model on a graph, they found that the epidemic threshold is proportional to the *spectral radius* of the adjacency matrix. Follow-up works verified this relation and broadened the discussion to more types of diffusion and related models. In [9] the \(S^*I^2V^*\) model was presented as a generalization of numerous virus propagation models of the literature. It was also made possible to generalize the result of [8] to that of generic virus models. Based on these works, several research studies have been presented on the epidemic control on networks, mainly focusing on developing *immunization* strategies (elimination of nodes) and *quarantine* strategies (elimination of edges). The eigenvalue perturbation theory was among the main analytical tools used; see for example [10,14,15].

Similar theoretical results to those discussed above have been given for ICM as well. Under discrete- or continuous-time ICM, it has been shown that the epidemic threshold depends on the *spectral radius* of a matrix built upon the edge transmission probabilities, termed as the *Hazard matrix* [11,12].

Related applications. Dealing with information diffusion and rumors gives rise to a series of computational and inference problems, including: credibility assessment of posts and users [42]; sentimental analysis on how individuals receive a piece of information; stance/role identification of users toward it; detection of rumors and their spreaders in content streams [43–45]; identification of influential users that could maximize the reach of a campaign by examining structural properties of the network alone or in combination with historical data (interaction traces) [5,46,47]; and finally, the development of countermeasures to suppress a rumor or information cascade [13,48], which is discussed in the technical part of the chapter.

24.3 MODELS OF INFORMATION CASCADES

Information cascades describe the dynamics of communication between individuals of a social network by capturing the way messages are shared and propagated among users. In all generality, an information cascade on a graph $G = (V, E)$ is a multivariate stochastic process $\{X_i(t) : i \in V, t \geq 0\}$ where $X_i(t) \in S$ denotes the state of user $i$ at time $t$, and $S$ is a state space that may be finite, countable, or uncountable. Depending on the specific model, the state of a user may refer to a binary quantity (e.g., $S = \{\text{Unaware, Informed}\}$), to the number of messages received during $[0, t]$ (in which case $S = \mathbb{N}$), or something more detailed regarding the message spread (e.g., $S = \mathbb{R}^d$ a low-dimensional representation...
of the content of the message). In all the models, we consider that users that did not participate at all in the cascade are in a default state $0 \in S$. As a rumor propagates through the network, the number of individuals participating in the cascade, called influence, will grow and eventually reach a saturation point. We use this quantity as our main quality metric:

Definition 24.1 (Influence $\sigma(S_0, t)$). Let $S_0 = \{i \in V : X_i(0) \neq 0\} \subset V$ be the set of influencers, i.e., users that are initially contagious. The influence of the set $S_0$ at time $t$ is defined as the total number of messages received by users of the social network before time $t$:

$$\sigma(S_0, t) = \mathbb{E}\left[\sum_{i \in V} 1\{X_i(t) \neq 0\}\right].$$  

(24.1)

In the following, we denote as $n = |V|$ the size of the social network, $E = |\mathcal{E}|$ the number of connections, $n_0 = |S_0|$ the number of initial influencers and the adjacency matrix of $G$ as $A \in \{0, 1\}^{n \times n}$ s.t. $A_{ij} = 1 \iff (i, j) \in \mathcal{E}$. Moreover, we denote as long-term influence the total number of received messages after the diffusion $\sigma(S_0) = \lim_{t \to +\infty} \sigma(S_0, t)$.

24.3.1 EARLY MODELS: VIRUSES SPREADING THROUGH SOCIAL NETWORKS

Epidemics are usually modeled using Markov processes [49], i.e., memoryless stochastic processes entirely defined by their transition matrix. This transition matrix defines the probability for each node to change state during an infinitesimal time window $[t, t + dt]$ (the simultaneous change of more than one node’s state is considered improbable). In the following, we thus use the notation:

$$X_i(t) : Y \to Z \text{ at rate } C_i(t)$$

(24.2)

to denote the stochastic transition rate $C_i(t) \geq 0$ of node $i \in \{1, \ldots, n\}$ at time $t \geq 0$ from state $Y$ to state $Z$, with $Y, Z \in S$.

Due to similarities between spreading phenomena, virus models have also been used to describe information cascades on social networks. We focus on two standard such models: the SI and SIR models, and we refer the reader to the recent review in [50] for more information on the vast epidemiology literature.

Susceptible-Infected model

The Susceptible-Infected (SI) model is the simplest epidemic model, in which nodes can be either (S)usceptible or (I)nfected. An infected node transmits the disease to one of its susceptible neighbor at a rate $\beta$, and once infected a node remains infected and thus contagious.

Model 24.1 (SI model). Let $G$ be a (possibly weighted) graph of $n$ nodes and adjacency matrix $A$. The SI model is a continuous-time Markov process $X(t) \in \{S, I\}^n$ with the following transition rate:

$$X_i(t) : S \to I \text{ at rate } \beta \sum_j A_{ij} X_j(t),$$

(24.3)

where $\beta$ is the transmission rate of the epidemic.

Because the nodes remain infected, a connected network will be totally infected at the end of the diffusion, and hence any set $S_0$ has influence $\sigma(S_0) = n$. 

Susceptible-Infected-Removed model
The Susceptible-Infected-Removed (SIR) model [51] is a widely used epidemic model designed for scenarios in which patients present immunity to the disease after their infection and recovery. A recovered person will not transmit the disease further nor will it be subject to reinfections. An additional state is thus added to the SI model and each node of the network is either (S)usceptible, (I)infected, or (R)emoved. At \( t = 0 \), a subset \( S_0 \) of \( n_0 \) nodes is infected. Then, each infected node will transmit the disease to its neighbors at rate \( \beta \), and recover at rate \( \delta \).

**Model 24.2 (SIR model).** Let \( G \) be a (possibly weighted) graph of \( n \) nodes and adjacency matrix \( A \). The SIR model is a continuous-time Markov process \( X(t) \in \{S,I,R\}^n \) with the following transition rates:

\[
X_i(t) : S \rightarrow I \text{ at rate } \beta \sum_j A_{ji} X_j(t) \\
X_i(t) : I \rightarrow R \text{ at rate } \delta.
\]

where \( \beta \) is the transmission rate of the epidemic and \( \delta \) is the recovery rate of nodes.

Usually, the graph is undirected and all edges have the same rate. More complex scenarios can be modeled using the inhomogeneous SIR model, in which each edge has its own transmission rate \( \beta_{ij} \) and each node its own recovery rate \( \delta_i \).

An alternative definition for this model is possible using infection times. One may see that each node gets infected at most once and recovers at most once as well. We can thus define, for each node \( i \), the time \( \tau^I_i \) at which it gets infected and the time \( \tau^R_i \) at which it recovers, with \( \tau^I_i, \tau^R_i \in \mathbb{R}_+ \cup \{ +\infty \} \). Then, \( \tau^I_i = 0 \) would indicate that user \( i \) is an influencer while \( \tau^I_i = +\infty \) would indicate that node \( i \) never got infected throughout the whole epidemic.

**Proposition 24.1.** For an SIR epidemic, the infection times \( \tau^I_i \) of not initially infected nodes verify the following equality:

\[
\forall i \notin S_0, \quad \tau^I_i = \min_{j \in \{1,\ldots,n\} : T_{ji} < D_j} (\tau^I_j + T_{ji}),
\]

where \( T_{ji} \) and \( D_j \) are independent exponential random variables of expected value \( 1/\beta \) and \( 1/\delta \), respectively, and \( \tau^I_i = +\infty \) if the set \( \{ j \in \{1,\ldots,n\} : T_{ji} < D_j \} \) is empty. Furthermore, the recovery time of each node \( i \) is:

\[
\tau^R_i = \tau^I_i + D_i.
\]

**Proof.** This result relies on the fact that a node is infected as soon as at least one of its infected neighbors transmits the infection to him. Because these events are independent, the times \( T_{ij} \) required for infection along the edges of the network are also independent. For more precisions, see e.g., [11].

### 24.3.2 INDEPENDENT CASCADES

Independent cascades were initially introduced as discrete-time diffusion processes [28], and later refined to more flexible continuous-time processes [7].

**Model 24.3 (Discrete-time independent cascades \( D\text{TI}\text{C}(\mathcal{P}) \)).** At time \( t = 0 \), only a set \( S_0 \) of influencers is infected. Given a matrix \( \mathcal{P} = (p_{ij})_{ij} \in [0,1]^{n \times n} \), each node \( i \) that receives the contagion at
time \( t \) may transmit it at time \( t + 1 \) along its outgoing edge \((i, j) \in E\) with probability \( p_{ij} \). Node \( i \) cannot infect its neighbors in subsequent rounds \( t' > t + 1 \). The process terminates when no more infections are possible.

The continuous version of independent cascades requires the definition of Hazard functions to describe the varying transmission rates along each edge of the network.

**Definition 24.2** (Hazard function \( F_{ij}(t) \)). For every edge \((i, j) \in E\) of the graph, \( F_{ij} \) is a nonnegative integrable function that describes the time-dependent stochastic transmission rate from node \( i \) to node \( j \), after \( i \)'s infection.

**Model 24.4** (Continuous-time independent cascades \( CTIC(F) \)). The \( CTIC(F) \) model is a stochastic diffusion process defined as follows: at time \( s = 0 \), only the influencer nodes in \( S_0 \) are infected. Then, each node \( i \) that receives the contagion at time \( \tau_i \) may transmit it at time \( s \geq \tau_i \) along an outgoing edge \((i, j) \in E\) with stochastic rate of occurrence \( F_{ij}(s - \tau_i) \).

The rest of this chapter will mainly focus on the analysis and control of such information cascades. For notational purposes, we denote as \( F = [F_{ij}] \) the \( n \times n \) Hazard matrix containing as elements the individual Hazard functions and, respectively, as \( F(t) = [F_{ij}(t)] \) the evaluation of all functions at a relative time-point \( t \) after each infection time \( \tau_i \). Essentially, network edges imply nonzero Hazard functions:

\[
(i, j) \in E \iff \exists t \geq 0 \text{ s.t. } F_{ij}(t) \neq 0.
\]  

(24.7)

Note that each Hazard function \( F_{ij} \) is always evaluated at a relative time-point initialized at the infection time \( \tau_i \) of the source node \( i \).

Similarly to SIR, independent cascades are monotonically increasing stochastic processes, and each node can only be infected once. We can thus define, for each node \( i \), the time \( \tau_i \) of its first infection, which may be infinite if the node never gets infected during the contagion. Unlike SIR, no epidemic states are explicitly mentioned in the notations of \( CTIC \) (the reader may compare Eqs. (24.5) and (24.8).

**Proposition 24.2.** For a Continuous-Time Independent Cascade \( CTIC(F, T) \), the infection times \( \tau_i \) of noninfluencer nodes verify the following equality:

\[
\forall i \notin S_0, \tau_i = \min_{j \in \{1,...,n\}} (\tau_j + T_{ji}).
\]  

(24.8)

where \( T_{ij} \in \mathbb{R}_+ \cup \{+\infty\} \) are independent random variables of subprobability density

\[
p_{ij}(t) = F_{ij}(t) \exp\left(-\int_0^t F_{ij}(s)ds\right).
\]  

(24.9)

**Proof.** This result is similar to Proposition 24.1 and relies on the same observation: a node is active as soon as at least one of its active neighbors activated him. Because these events are independent (hence the name of the model), the times \( T_{ij} \) required for activation along the edges of the network are also independent. For more precisions, see for example [52].

In general, \( p_{ij}(t) \) is not a probability density over \( \mathbb{R}_+ \) as it does not integrate to one, and \( P(T_{ij} = +\infty) = 1 - \int_0^{+\infty} p_{ij}(t)dt = \exp(-\int_0^{+\infty} F_{ij}(t)dt) \). Proposition 24.2 provides a simple mechanism for simulating \( CTIC \), as one can first draw one independent random variable \( T_{ij} \) per edge, and then use a shortest-path algorithm to compute the infection times \( \tau_i \) for each node of the network.
In what follows, we focus on this model due to its expressiveness and broad use in modern social network studies. However, the large-scale dynamics of all diffusion models are relatively similar and exhibit the same threshold behavior.

### 24.4 LARGE-SCALE DYNAMICS OF INDEPENDENT CASCADES

At the scale of the network, the emergent behavior of information cascades displays several typical characteristics that are common in most diffusion processes, including epidemics and computer viruses. For instance, Fig. 24.1 shows the number of identified cases of Ebola during a recent crisis, the number of queries for “Pokemon go” when the game became viral, and the simulation of an independent cascade (see Model 24.4 in Section 24.3). All these diffusion processes exhibit similar behavior:

1. **Explosive start:** The cascade starts with an exponential increase and quickly reaches a nonnegligible amount.
2. **Saturation point:** After a sharp increase during the early phase of the diffusion, the process reaches a saturation point and comes to a halt. Note that, for information cascades, a residual activity may produce a linear slope after the end of the diffusion. However, we ignore this aspect in our study.

As a consequence, we focus on four main characteristics of interest to describe the large-scale dynamics of information cascades:

1. **Existence:** Is the cascade powerful enough to enter the explosive phase?
2. **Saturation point:** What is the final reach of the cascade?
3. **Time for action:** When is the explosion taking place?
4. **Explosive rate:** How fast is the initial exponential increase of the cascade?

These four characteristics are summarized in a simulated toy example on Fig. 24.1C. In the following sections, we provide estimates of these quantities depending on the diffusive properties of the process as well as the structure of the social network.

#### 24.4.1 EXISTENCE OF A SUPERCRITICAL CASCADE

Intuitively, an information cascade may only sustain itself if, on average, people that receive the message share it to more than one of their neighbors. When the network connectivity is too low, the cascade cannot reach a large audience before dying out. This is highlighted by the following upper bound relating a measure of network connectivity introduced in [12], the **Hazard radius**, to the long-term influence.

**Definition 24.3 (Hazard radius \( \rho_H(F) \)).** For a diffusion process \( CTIC(F) \), \( \rho_H(F) \) is the largest eigenvalue of the symmetrized and integrated Hazard matrix:

\[
\rho_H(F) = \rho \left( \int_0^{+\infty} \frac{F(t) + F(t)^T}{2} dt \right),
\]  

(24.10)

where \( \rho(\cdot) = \max_i |\lambda_i| \) and \( \lambda_i \) are the eigenvalues of the input matrix.

\[\blacksquare\]
FIG. 24.1
Main large-scale characteristics of diffusion processes appearing in real and simulated cascades. (A) Number of Ebola cases in Guinea, Liberia, and Sierra Leone (source: World Health Organization). (B) Number of searches for the query “Pokemon go” on the Google search engine (source: Google Trend). (C) Simulation of a Continuous-Time Independent Cascade (see Model 24.4). The main large-scale characteristics highlighted in our analysis are also summarized: existence of outbreak, time before the explosion, explosive rate, and saturation point.
When all edges of the social network have an identical Hazard function $F_{ij}(t)$, the Hazard radius is proportional to the spectral radius of the adjacency matrix, which has been shown to drive the spread of epidemics [9]. The following proposition extends this result to independent cascades.

**Proposition 24.3.** Let $S_0 \subset V$ be a set of $n_0$ influencer nodes, and $\rho_H(F)$ the Hazard radius of a CTIC($F$). Then, if $\rho_H(F) < 1$, the influence of $S_0$ in CTIC($F$) is upper bounded by:

$$\sigma(S_0) \leq n_0 + \sqrt{\frac{\rho_H(F)}{1 - \rho_H(F)}} \sqrt{n_0(n - n_0)}.$$  

(24.11)

**Proof.** This result relies on a nontrivial vector inequality between the activation probabilities $Z_i$ at the end of the epidemic, defined as:

$$Z_i = P(\tau_i < +\infty).$$  

(24.12)

Note that

$$\|Z\|_1 = \sum_i E[1\{\tau_i < +\infty\}] = \sigma(S_0),$$  

(24.13)

and any result on the vector $Z$ will easily translate into a result on the influence. Proposition 24.2 leads to a relationship between the $Z_i$, as for any vector $c$, $\min_{j \in \{1, \ldots, n\}} c_j < +\infty \iff \exists j \in \{1, \ldots, n\}$ s.t. $c_j < +\infty$, and thus

$$1\{\tau_i < +\infty\} = 1\{\min_{j \in \{1, \ldots, n\}} (\tau_j + T_{ji}) < +\infty\} = 1 - \prod_j (1 - 1\{\tau_j < +\infty\} 1\{T_{ji} < +\infty\}).$$  

(24.14)

Taking the expectation and using the Fortuin-Kasteleyn-Ginibre (FKG) inequality [53], a well-known result of mathematical physics, to prove the positive correlation between the variables $1\{\tau_i < +\infty\}$, the following inequality arises after a short calculation:

$$\forall i \notin S_0, \ Z_i \leq 1 - \exp \left( - \sum_j H_{ji}Z_j \right).$$  

(24.15)

This inequality upper bounds the expected activation of a node with the expected activation of its neighbors, and can be turned into a bound on the norm of $Z$ using the spectral radius of the matrix $H$. The final step of the proof is rather calculatory and relies on Jensen’s inequality and the definition of the spectral radius for symmetric matrices. The complete derivation is available in [12].

Hence, the independent cascade is subcritical when $\rho_H(F) < 1$, and the number of active users remains negligible compared to the size of the network: $\sigma(S_0) = O(\sqrt{n}) \ll n$. Note that we assume the number of influencer nodes $n_0$ is bounded and does not depend on $n$.

### 24.4.2 Long-term Behavior of Independent Cascades

When the cascade is efficient enough to propagate to a large proportion of the network, it displays a sharp increase before saturating to a limit value. Although the precise value of this limit influence is hard to evaluate, several upper bounds have been provided and proven in the literature [12,54]. We now provide such a result relating the long-term influence to the Hazard radius of the cascade.
**Proposition 24.4.** Let $S_0 \subseteq \mathcal{V}$ be a set of $n_0$ influencer nodes, and $\rho_{\mathcal{H}}(\mathcal{F})$ the Hazard radius of a CTIC($\mathcal{F}$). Then, if $\rho_{\mathcal{H}}(\mathcal{F}) > 1$, the long-term influence of $S_0$ in CTIC($\mathcal{F}$) is upper bounded by:

$$\sigma(S_0) \leq n_0 + \gamma(n - n_0) + c_n \sqrt{n_0(n - n_0)},$$

(24.16)

where $c_n = \sqrt{\frac{n}{1 - \eta}}, \eta = (1 - \gamma)\rho_{\mathcal{H}}(\mathcal{F})$ and $\gamma \in [0, 1]$ is the unique positive solution of the equation:

$$\gamma = 1 - \exp\left(-\rho_{\mathcal{H}}(\mathcal{F})\gamma\right).$$

(24.17)

**Proof.** This result is also a consequence of Eq. (24.15) relating the expected activations $Z_i$. See [12].

In essence, the proportion of active nodes after the cascade is negligible when $\rho_{\mathcal{H}}(\mathcal{F}) < 1$, and at most $\gamma$ when $\rho_{\mathcal{H}}(\mathcal{F}) > 1$, where $\gamma$ is defined by the implicit equation $\gamma = 1 - \exp\left(-\rho_{\mathcal{H}}(\mathcal{F})\gamma\right)$. Fig. 24.2 shows the proportion $\gamma$ of Proposition 24.4 with respect to the Hazard radius $\rho_{\mathcal{H}}(\mathcal{F})$.

### 24.4.3 Explosive Dynamics in the Supercritical Regime

Finally, the intermediate regime when the cascade grows exponentially can be analyzed using a modified version of the Hazard radius, known as the Laplace Hazard radius.

**Definition 24.4 (Laplace Hazard matrix $\mathcal{L}(s)$).** Let $p_{ij}$ be the edge transmission probabilities defined in Eq. (24.9). For $s \geq 0$, let $\mathcal{L}(s)$ be the $n \times n$ matrix, called Laplace Hazard matrix, whose coefficients are:

$$\mathcal{L}_{ij}(s) = \begin{cases} -\hat{p}_{ij}(s) \left(\int_0^\infty p_{ij}(t)dt\right)^{-1} \ln\left(1 - \int_0^\infty p_{ij}(t)dt\right) & \text{if } (i, j) \in \mathcal{E}, \\ 0 & \text{otherwise}, \end{cases}$$

(24.18)

where $\hat{p}_{ij}(s)$ denotes the Laplace transform of $p_{ij}$ defined for every $s \geq 0$ by $\hat{p}_{ij}(s) = \int_0^\infty p_{ij}(t)e^{-st}dt$. 

**FIG. 24.2**

Upper bound on the saturation point. Function $\gamma$ defined in Eq. 24.17. When $\rho_{\mathcal{H}}(\mathcal{F}) < 1$, the function is equal to 0, then increases and saturates to $\gamma = 1$ as $\rho_{\mathcal{H}}(\mathcal{F})$ tends to infinity.
Definition 24.5 (Laplace Hazard radius $\rho_L(s)$). For a diffusion process $\mathcal{CTIC}(\mathcal{F})$ and $s \geq 0$, $\rho_L(s)$ is the largest eigenvalue of the symmetrized Laplace Hazard matrix:

$$\rho_L(s) = \rho \left( \frac{L(s) + L(s)^T}{2} \right),$$

(24.19)

where $\rho(\cdot) = \max_i |\lambda_i|$ and $\lambda_i$ are the eigenvalues of the input matrix.

This concept is slightly more complicated than the Hazard radius. When $s = 0$, the Laplace Hazard radius coincides with the Hazard radius: $\rho_L(0) = \rho_H(\mathcal{F})$. However, when $s$ is large, the Laplace Hazard radius captures the short-term behavior of the hazard function by reducing the impact of long times through the Laplace transform. Quite surprisingly, the explosive rate of the cascade is upper bounded by the inverse value $\rho_L^{-1}(1)$. This is discussed by the following proposition.

Proposition 24.5. Let $t \geq 0$, $S_0 \subset \mathcal{V}$ be a set of $n_0$ influencer nodes, and $\rho_L$ the Laplace Hazard radius. Then, the short-term influence of $S_0$ in $\mathcal{CTIC}(\mathcal{F})$ at time $t$ is upper bounded by:

$$\sigma(S_0, t) \leq n_0 + (2n_0)^{1/3}(n - n_0)^{2/3} \exp \left( \rho_L^{-1}(1) t \right).$$

(24.20)

Proof. This result relies on a similar equation to Eq. (24.15) describing the dynamics of the cascade instead of its long-term stable regime. More specifically, Proposition 24.2 shows that, for any $t \geq 0$, the variables $1\{\tau_i < t\}$ are related according to:

$$1\{\tau_i < t\} = 1 - \prod_j \left( 1 - 1\{\tau_j + T_{ji} < t\} \right).$$

(24.21)

Now, denoting as $Z_i(t) = \mathbb{P}(\tau_i < t)$ the probability that node $i$ is active at time $t$, one may show the following vectorial inequality relating the variables $Z_i(t)$:

$$Z_i(t) \leq 1 - \exp \left( - \sum_j (\mathcal{F}_{ji} \ast Z_j)(t) \right),$$

(24.22)

where $(f \ast g)(t) = \int_{\mathbb{R}} f(s)g(t - s)ds$ is the convolution product. From this inequality, one may prove an upper bound on the Laplace transform of the influence $\hat{\sigma}(s) = \int_0^{+\infty} \sigma(S_0, t)e^{-st}dt$, directly translating into an upper bound on the exponential increase of the influence. Again, the complete derivation is available in [11].

This result has two implications (for more precise results see [11]):

- First, the influence is at most increasing at an exponential rate of $\rho_L^{-1}(1)$.
- Second, this also provides a characteristic time under which the cascade is still in its early phase. More precisely, before the critical time

$$t \leq \frac{\ln n}{3\rho_L^{-1}(1)},$$

(24.23)

the cascade is subcritical and the influence is negligible: $\sigma(S_0, t) = \mathcal{O}(n^{2/3})$. 

24.5 MONITORING INFORMATION CASCADES

Having presented the fundamental theoretical properties of diffusion processes related to information propagation over networks, we now discuss an efficient approach to the generic problem of optimizing influence (maximizing or minimizing) using actions that can shape, i.e., modify, the activity of single users. For instance, a marketing campaign may have a certain advertisement budget that can be used on targeted users of a social network. While these targeted resources are usually represented as new influencer nodes that will spread the piece of information, we rather consider the more refined and general case in which each resource will essentially alter the Hazard functions $F_{ij}$ associated to a target node $i$, thus increasing, or decreasing, the probability for $i$ to propagate by sharing the information with its neighbors.

Our generic framework assumes that a set of feasible Hazard matrices $F \subset \mathbb{R}_+ \rightarrow \mathbb{R}^{n \times n}$ is available to the administrator. This set virtually contains all admissible policies that one could apply to the network. Then, the concern is to find the Hazard matrix $F \in F$ that minimizes, or maximizes depending on the task of interest, the influence. In Section 24.7 we show that two problems that have been a major focus of the literature so far, namely the edge-deletion problem [14] and the node-immunization problem [15] are particular instances of this framework. Note that this framework is generic enough to describe complex strategies that may use several immunization options by deploying simultaneously resources of different types (removal of edges, nodes, partial immunization, etc.).

**Problem 24.1 (Determining the optimal feasible policy).** Given a graph $G$, a number of influencers $n_0$, and a set of admissible policies $F$, find the optimal policy:

$$F^* = \arg\min_{F \in F} \sigma^*_{n_0}(F),$$

where $\sigma^*_{n_0}(F) = \max\{\sigma(S_0) : S_0 \subseteq V \text{ and } |S_0| = n_0\}$ is the optimal influence (according to Eq. (24.24) this is the minimum) over any possible set of $n_0$ influencer nodes.

Problem 24.1 cannot be solved exactly in polynomial time. The exact computation of the maximum influence $\sigma^*_{n_0}(F)$ is already a hard problem on its own, and minimizing this quantity adds an additional layer of complexity due to the nonconvexity of the maximum influence w.r.t. the Hazard matrix (note: $F \mapsto \sigma^*_{n_0}(F)$ is positive, upper bounded by $n$ and not constant).

**Proposition 24.6.** For any size of the set of influencers $n_0$, the computation of $\sigma^*_{n_0}(F)$ is #P-hard.

**Proof.** We prove the theorem by reduction from a known #P-hard function: the computation of the influence $\sigma(S_0)$ given a set of influencers $S_0$ of size $n_0$ (see Theorem 1 of [55]). Indeed, let $CTIC(F)$ be an independent cascade defined on $G = (V, E)$. We can construct a new graph $G' = (V', E')$ as follows: for each influencer node $i \in S_0$, add a directed chain of $n$ nodes $\{v_{i,1}, \ldots, v_{i,n}\} \subseteq V'$ and connect $v_{i,m}$ to $i$ by letting the transmission probabilities along the edges be all equal to one. Then, the maximum influence $\sigma^*_{n_0}$ is achieved with the nodes $S'_0 = \{v_{i,1} : i \in S_0\}$ as influencer, and $\sigma^*_{n_0} = n n_0 + \sigma(S_0)$. The result follows from the #P-hardness of computing $\sigma(S_0)$ given $S_0$.

The standard way to approximate the maximum influence is to employ incremental methods where the quality of each potential influencer is assessed using a Monte Carlo approach. In the following, we assume that the feasible set $F$ is convex and included in a ball of radius $R$. Also, the requirement of Eq. (24.7), that network edges correspond to nonzero Hazard functions, holds for every feasible policy $F \in F$. Therefore, the number of edges $E$ upper bounds the number of nonzero Hazard functions for any $F \in F$. 

\[\]
Remark 24.1. Although Problem 24.1 focuses on the minimization of the maximum influence, the algorithm presented in this paper is also applicable to the opposite task of influence maximization. Having a common ground for solving these opposite problems can be useful for applications where both opposing aims can interest different actors, e.g., in market competition. For the maximization, our algorithm would use a gradient ascent instead of a gradient descent optimization scheme. While the performance of the algorithm in that case may be competitive to state-of-the-art influence maximization algorithms, the nonconvexity of this problem prevents us from providing any theoretical guarantees regarding the quality of the final solution.

24.6 AN ALGORITHM FOR REDUCING INFORMATION CASCADES

As has been mentioned, solving exactly the influence optimization problem is computational intractable. Here, we propose to exploit the upper bound given in Proposition 24.4 as a heuristic for approximating the maximum influence. This approach can be seen as a convex relaxation of the original NP-Hard problem, and allows the use of convex optimization algorithms for this particular problem. The relaxed optimization problem thus becomes:

$$F^* = \arg \min_{\mathcal{F} \in \mathbb{F}} \rho_H(F).$$

(24.25)

When the feasible set $\mathbb{F}$ is convex, this optimization problem is also convex and our proposed method called NetShape uses a simple projected subgradient descent (see e.g. [56]) in order to find its minimum and make sure that the solution lays in $\mathbb{F}$. However, special care should be taken to perform the gradient step because although the objective function $\rho_H(F)$ admits a derivative w.r.t. the norm

$$\| \mathcal{F} \| = \sqrt{\sum_{i,j} \left( \int_0^{+\infty} |F_{ij}(t)| dt \right)^2},$$

(24.26)

the space of matrix functions equipped with this norm is only a Banach space in the sense that the norm $\| \mathcal{F} \|$ cannot be derived from a well-chosen scalar product. Because gradients only exist in Hilbert spaces, gradient-based optimization methods are not directly applicable.

In the NetShape algorithm, the gradient and projection steps are performed on the integral of the Hazard functions $\int_0^{+\infty} F_{ij}(t) dt$ by solving the optimization problem bellow:

$$F^* = \arg \min_{\mathcal{F} \in \mathbb{F}} \left\| \int_0^{+\infty} \left( \tilde{F}(t) - F(t) \right) dt + \eta u_F u_F^T \right\|_2,$$

(24.27)

where $\eta > 0$ is a positive gradient step, $u_F$ is the eigenvector associated to the largest eigenvalue of the matrix $\int_0^{+\infty} \frac{F(t)+\tilde{F}(t)}{2} dt$, and $u_F u_F^T$ is a subgradient of the objective function, as provided by the following proposition.
Proposition 24.7. A subgradient of the objective function \( f(M) = \rho \left( \frac{M + M^T}{2} \right) \) in the space of integrated Hazard functions, where \( M \) is a matrix, is given by the matrix:

\[
\nabla f(M) = u_M u_M^T, \tag{24.28}
\]

where \( u_M \) is the eigenvector associated to the largest eigenvalue of the matrix \( \frac{M + M^T}{2} \).

Proof. For any matrix \( M \), let \( f(M) = \rho \left( \frac{M + M^T}{2} \right) = \max_{x: \|x\|_2 = 1} x^T M x \), and \( u_M \) be such an optimal vector. Then, we have

\[
\begin{align*}
\frac{f(M + \varepsilon)}{\varepsilon} & = u_M^T (M + \varepsilon) u_M + \varepsilon u_M^T M u_M \\geq u_M^T (M + \varepsilon) u_M \Rightarrow \nabla f(M) = u_M u_M^T.
\end{align*}
\]

Algorithm 24.1 NETSHAPE METAALGORITHM

Input: feasible set \( \mathbb{F} \subset \mathbb{R}_+ \rightarrow \mathbb{R}^{n \times n}_+ \), radius \( R > 0 \) of \( \mathbb{F} \), initial Hazard matrix \( \mathcal{F} \in \mathbb{F} \), approx. parameter \( \epsilon > 0 \)
Output: Hazard matrix \( \mathcal{F}^* \in \mathbb{F} \\
1: \quad \mathcal{F}^* \leftarrow \mathcal{F} \\
2: \quad T \leftarrow \left\lceil \frac{R^2}{\epsilon^2} \right\rceil \\
3: \quad \text{for } i = 1 \text{ to } T - 1 \text{ do} \\
4: \quad u_{\mathcal{F}} \leftarrow \text{compute the eigenvector associated to the spectral radius } \rho_{\mathcal{H}}(\mathcal{F}) \\
5: \quad \eta \leftarrow \frac{R}{\sqrt{i}} \\
6: \quad \mathcal{F} \leftarrow \arg\min_{\mathcal{F} \in \mathbb{F}} \left\| \int_0^{+\infty} (\hat{\mathcal{F}}(t) - \mathcal{F}(t)) \, dt + \eta u_{\mathcal{F}} u_{\mathcal{F}}^T \right\|_2 \\
7: \quad \mathcal{F}^* \leftarrow \mathcal{F}^* + \mathcal{F} \\
8: \quad \text{end for} \\
9: \quad \text{return } \frac{1}{T} \mathcal{F}^*
\]

The projection step of line 6 in Algorithm 24.1 is an optimization problem on its own, and the NetShape algorithm is practical if and only if this optimization problem is simple enough to be solved. In the next sections we will see that, in many cases, this optimization problem can be solved in near linear time w.r.t. the number of edges of the network (i.e., \( O(E \ln E) \)), and is equivalent to a projection on a simplex.

24.6.1 CONVERGENCE AND SCALABILITY

Due to the convexity of the optimization problem in Eq. (24.25), NetShape finds the global minimum of the objective function and, as such, may be a good candidate to solve Problem 24.1. The complexity of the NetShape algorithm depends on the complexity of the projection step in Eq. (24.27). Each step of the gradient descent requires the computation of the first eigenvector of an \( n \times n \) matrix, which can be computed in \( O(E \ln E) \), where \( E \) is the number of edges of the underlying graph. In most real applications, the underlying graph on which the information is diffusing is sparse, in the sense that its number of edges \( E \) is small compared to \( n^2 \).

Proposition 24.8. Assume that \( \mathbb{F} \) is a convex set of Hazard matrices included in a ball of radius \( R > 0 \) w.r.t. the norm in Eq. (24.26), and that the projection step in Eq. (24.27) has complexity at most \( O(E \ln E) \). Then, the NetShape algorithm described in Algorithm 24.1 converges to the minimum of Eq. (24.25). Moreover, the complexity of the algorithm is \( O\left( \frac{R^2}{\epsilon^2} E \ln E \right) \).
Proof. This is a direct application of the projected subgradient descent to the problem:

\[ \mathcal{H}^* = \arg \min_{\mathcal{H} \in \mathbb{H}} \rho \left( \frac{\mathcal{H} + \mathcal{H}^\top}{2} \right), \]  

(24.29)

where \( \mathbb{H} = \left\{ \int_0^{+\infty} \mathcal{F}(t) dt \in \mathbb{R}^{n \times n} : \mathcal{F} \in \mathcal{F} \right\} \) is the set of feasible Hazard matrices. The convergence rate of such an algorithm can be found in [56].

Remark 24.2. The corresponding maximization problem is not convex anymore and only convergence to a local maximum can be expected. However, when the changes in the Hazard functions are relatively small (e.g., inefficient control actions, or only a limited number of treatments available to distribute), then NetShape achieves fairly good performance.

24.7 CASE STUDIES

In this section, we illustrate the generality of our framework by reframing well-known diffusion suppression problems that can find application in rumor control that has been discussed extensively in this chapter. Using Problem 24.1 we derive the corresponding variants of the NetShape algorithm.

For simplicity, we denote as \( M \odot M' \) the Hadamard product between the two matrices (i.e., coordinate-wise multiplication), as \( \Delta = \int_0^{+\infty} \left( \hat{\mathcal{F}}(t) - \mathcal{F}(t) \right) dt \) the matrix with the integrated coordinate-wise difference of two Hazard matrices in time, and as \( 1 \in \mathbb{R}^n \) the all-one vector (see notations in Table 24.1).

24.7.1 PARTIAL QUARANTINE

The quarantine approach aims to remove a small number of edges in order to minimize the spread of the contagion. This strategy is highly interventional in the sense that it totally removes edges, but in order to be practical it has to remain at low scale and affect a small amount of edges. This is the reason why it is mostly appropriate for dealing with the initial very few infections. The partial quarantine setting is a relaxation where one is interested in decreasing the transmission probability along a set of targeted edges by using local and expensive actions.

Definition 24.6 (Partial quarantine). Consider that a marketing campaign has \( k \) control actions to distribute in a network \( \mathcal{G} = (\mathcal{V}, \mathcal{E}) \). For each edge \((i,j) \in \mathcal{E}\), let \( \mathcal{F}_{ij} \) and \( \hat{\mathcal{F}}_{ij} \) be the Hazard matrices before and after applying control actions, respectively. If \( X \in [0, 1]^{n \times n} \) is the control actions matrix and \( X_{ij} \) represents the amount of suppressive action taken on edge \((i,j)\), then the set of feasible policies can be expressed as:

\[ \mathbb{F} = \{ (1 - X) \odot \mathcal{F} + X \odot \hat{\mathcal{F}} : X \in [0, 1]^{n \times n}, \|X\|_1 \leq k \}. \]

(24.30)
Example. For a nonnegative scalar $\epsilon \geq 0$, we may consider $\hat{F} = (1 - \epsilon)F$ in order to model the suppression of selected transmission rates; formally:

$$\mathbb{F} = \{(1 - \epsilon X) \odot F : X \in [0,1]^{n \times n}, \|X\|_1 \leq k\}. \quad (24.31)$$

Importantly, for the special case where $\epsilon = 1$, this problem becomes equivalent to the setting discussed in [10,14].

A straightforward adaptation of Algorithm 24.1 to this setting leads to the NetShape algorithm for partial quarantine described in Algorithm 24.2. The projection step is performed by Algorithm 24.3 on the flattened versions $x', \delta, y$ of the matrices $X', \Delta$, and $Y$, and the parameter $R$ is chosen to upper bound $\max_{F' \in \mathbb{F}} \|F' - F\|_2 = \max_{X \in [0,1]^{n \times n}, \|X\|_1 \leq k} \|X \odot \Delta\|_2$.

Lemma 24.1. The projection step of Algorithm 24.1 for the partial quarantine setting of Definition 24.6 is:

$$X^* = \arg \min_{X' \in [0,1]^{n \times n}, \|X'\|_1 \leq k} \|X' \odot \delta - y\|_2,$$

where $\delta$ and $y$ are flattened versions of, respectively, $\Delta$ and $Y = X \odot \Delta - \eta u_F u_F^T$. Moreover, this problem can be solved in time $O(E \ln E)$ with Algorithm 24.3, where $E$ is the number of edges of the network.

Proof. Eq. (24.32) directly follows from Eq. (24.27) and the definition of $\mathbb{F}$. Algorithm 24.3 is an extended version of the $L_1$-ball projection algorithm of [57]. Karush-Kuhn-Tucker (KKT) conditions for the optimization problem of Eq. (24.32) imply that $\exists z > 0$ s.t. $\forall i, x'_i = \max\{0, \min\{2\hat{F}_i\}, 1\}$. The algorithm is a simple linear search for this value. Finally, the sorting step (Algorithm 24.3, line 5) has the highest complexity $O(E \ln E)$, and the loops perform at most $2E$ iterations, hence an overall complexity $O(E \ln E)$.

Algorithm 24.2 NETSHAPE PARTIAL QUARANTINE PROBLEM

**Input:** graph $G = (V,E)$, matrices of Hazard functions before and after treatment $F, \hat{F} \in \mathbb{F}$, approximation parameter $\epsilon > 0$, number of treatments $k$

**Output:** matrix of Hazard functions $F^* \in \mathbb{F}$

1: $X \leftarrow 0, X^* \leftarrow 0$
2: $F \leftarrow \int_0^{+\infty} F(t)dt$
3: $\Delta \leftarrow \int_0^{+\infty} (\hat{F}(t)dt - F(t))dt$
4: $R \leftarrow \sqrt{k} \max_{ij} \Delta_{ij}$
5: $T \leftarrow \left\lceil \frac{R^2}{\epsilon^2} \right\rceil$
6: for $i = 1$ to $T - 1$
7: $M \leftarrow F + X \odot \Delta$
8: $u \leftarrow$ the largest eigenvector of $\frac{1}{T}(M + M^T)$
9: $Y \leftarrow X \odot \Delta - \frac{R}{\sqrt{i}} uu^T$
10: $X \leftarrow \arg \min_{X' \in [0,1]^{n \times n}, \|X'\|_1 \leq k} \|X' \odot \delta - y\|_2$ // projection step (Algorithm 24.3)
11: $X^* \leftarrow X^* + X$
end for
13: return $F^* = (1 - \frac{1}{T}X^*) \odot F + \frac{1}{T}X^* \odot \hat{F}$
Algorithm 24.3 PROJECTION STEP FOR THE PARTIAL QUARANTINE PROBLEM

**Input:** \( \delta, y \in \mathbb{R}^E \), budget \( k \in (0, E) \)

**Output:** control actions vector \( x' \)

1. for \( i = 1 \) to \( E \) do
2. \( \mu_i \leftarrow 2\delta_i y_i \)
3. \( \mu_{E+i} \leftarrow 2\delta_i (y_i - \delta_i) \)
4. end for
5. sort \( \mu \) into \( \mu_{\pi(1)} \geq \mu_{\pi(2)} \geq \cdots \geq \mu_{\pi(2E)} \)
6. \( d \leftarrow 0 \)
7. \( s \leftarrow 0 \)
8. \( i \leftarrow 1 \)
9. while \( s < k \) and \( \mu_{\pi(i)} \geq 0 \) do
10. \( d \leftarrow d + 1 \{ \pi(i) \leq E \} \frac{1}{2\delta_{\pi(i)}} - 1 \{ \pi(i) > E \} \frac{1}{2\delta_{\pi(i)} - E} \)
11. \( s \leftarrow s + d(\mu_{\pi(i)} - \mu_{\pi(i+1)}) \)
12. \( i \leftarrow i + 1 \)
13. end while
14. \( z \leftarrow \max\{0, \mu_{\sigma(i)} + \frac{s-k}{d}\} \)
15. return \( x' \) s.t. \( x'_i = \max\{0, \min\{\frac{2\delta_i y_i - z}{2\delta_i^2}, 1\}\} \)

24.7.2 PARTIAL NODE IMMUNIZATION

More often, control actions can only be performed on the nodes rather than the network edges that was the case of the previous section. For example, imagine advertising campaigns that aim to enhance the diffusion of a product or, more relevant to the suppressive scenario, decision-makers that debunk false information targeting specific influencer nodes. In that case, the effect of the control actions must be aggregated over nodes in the following way.

**Definition 24.7 (Partial node immunization).** Consider that a control campaign has \( k \) control actions to distribute in a network \( G = (V, E) \). For each edge \((i, j) \in E\), let \( \mathcal{F}_{ij} \) and \( \mathcal{F}^\#_{ij} \) be the Hazard matrices before and after applying control actions, respectively. If \( x \in [0, 1]^n \) is the control actions vector and \( x_i \) represents the amount of suppressive action taken on node \( i \), then we express the set of feasible policies as:

\[
\mathcal{F} = \left\{ (1 - x^T) \odot \mathcal{F} + x^T \odot \mathcal{F}^\# : x \in [0, 1]^n, \|x\|_1 \leq k \right\}. \tag{24.33}
\]

This setting corresponds to partial quarantine in which all outgoing edges of a node are impacted by a single control action. When \( \mathcal{F}^\# = 0 \), this problem corresponds to the node removal problem (or vaccination), that consists in removing \( k \) nodes from the graph in advance in order to minimize a future contagion (see \([15]\)).

Given a vector \( x \), the projection problem to solve is:

\[
x^* = \arg\min_{x' \in [0, 1]^n, \|x'\|_1 \leq k} \left\| (x'^T) \odot \Delta - Y \right\|_2
\]

\[
= \arg\min_{x' \in [0, 1]^n, \|x'\|_1 \leq k} \sum_i x_i^2 \left( \sum_j \Delta_{ij}^2 \right) - 2x_i \left( \sum_j \Delta_{ij} Y_{ij} \right)
\]

\[
= \arg\min_{x' \in [0, 1]^n, \|x'\|_1 \leq k} \left\| x' \odot \delta' - y' \right\|_2, \tag{24.34}
\]
where \( \delta'_i = \sqrt{\sum_j \Delta^2_{ij}} \) and \( y'_i = \frac{\sum_j \Delta_y y_{ij}}{\sqrt{\sum_j \Delta^2_{ij}}} \). Hence we can apply the projection step of Algorithm 24.3 for the partial node immunization problem using \( \delta' \) and \( y' \), and its complexity is \( O(n \ln n) \).

Remark 24.3. Because the upper bound of Proposition 24.4 holds as well for SIR epidemics [51] (see also [11]), this setting may also be used to reduce the spread of a disease using, for example, medical treatments or vaccines. More specifically, the Hazard matrix for an SIR epidemic is the following:

\[
H = \ln \left( 1 + \frac{\beta}{\delta} \right) A, \tag{24.35}
\]

where \( \delta \) is the recovery (or removal) rate and \( \beta \) is the transmission rate along edges of the network, and \( A \) the adjacency matrix. Then, a medical treatment may increase the recovery rate \( \delta \) for targeted nodes, thus decreasing all Hazard functions on its outgoing edges, and the partial node immunization setting is applicable.

### 24.8 EXPERIMENTS

#### 24.8.1 EXPERIMENTAL SETUP AND EVALUATION

In this section, we provide empirical evidence for the discussion of this chapter on controlling independent cascades under the ICM. We set the focus of this empirical evaluation in the offline partial node immunization problem under the ICM, as described in Section 24.7.2, and we are interested to see in practice the performance gains of the NetShape algorithm when compared to other baseline and state-of-the-art alternative policies.

**Compared policies.** We provide comparative experimental results against several strategies, namely:

(i) **Rand:** random selection of nodes;
(ii) **Degree:** selection of \( k \) nodes with highest out-degree;
(iii) **WeightedDegree:** selection of \( k \) nodes with highest sum of outgoing edge weight \( w_{ij} = \int_0^{+\infty} F_{ij}(t) dt \). This strategy can also be seen as the optimization of the first influence lower bound \( LB_1 \) of [54].
(iv) **NetShield** algorithm [15]. Given the adjacency matrix of a graph, this outputs the best \( k \)-nodes to totally immunize so as to decrease the vulnerability of the graph. This is done by assigning to each node a shield value that is high for nodes with high eigenscore and no edges connecting them. Note that, despite the fact that NetShield is tailored for immunization on unweighted graphs, it is not general enough to account for weighted edges and partial immunization as in our experimental setting.

**Network datasets.** The evaluation is performed on three benchmark real datasets (see Table 24.2) and the results are presented in subfigures of Fig. 24.4:

(a) a network of “friends lists” from Facebook [58];
(b) the Gnutella peer-to-peer file sharing network [58],
(c) the who-trust-whom online review site Epinions.com;
Table 24.2 Datasets: Details of the Benchmark Real Networks

<table>
<thead>

</tbody>
</table>

The last column is the size of the strongly connected component.

(d) a synthetic random network of \(n = 500\) nodes forming group structure (stochastic block-diagonal) that has been generated as follows. First, 10 equally-sized Erdös-Rényi clusters were independently formed with intracluster edge creation probability \(p_{\text{inter}} = 0.1\). Then, their adjacency matrices were used to compose a block-diagonal structure with uniform intercluster rewiring probability \(p_{\text{intra}} = 0.001\). Fig. 24.3A shows the structure of the final adjacency matrix (as having binary edge weights).

Note that the above networks only provide an unweighted adjacency matrix, thus only the existence, or not, of an edge between a pair of nodes is known. NetShape and the analysis of Section 24.5 is generally covering time-variable propagation functions between nodes. However, without loss of generality and for the sake of simplifying the experimental setup, we decided to use a simple class of propagation functions. For the generation of the matrix of edge-transmission probability rates \(\{p_{ij}\}\) we use a trivalency model, according to which, the \(p_{ij}\) values are drawn chosen uniformly at random from a small set of constants. In our case that is set to \(\{p_{\text{low}}, p_{\text{med}}, p_{\text{high}}\}\) and the specific used values are mentioned explicitly for each dataset at the figures’ captions.

Each treatment unit of the budget can be assigned to a single node and, here, we assume that it can cause a fixed decrease to the node’s transmission probability rates along all its outgoing edges (70% for the SBD10ER and 50% for the real networks).

In the experiments we evaluate the efficiency of the immunization policies on the basis of two measures, for both of which lower values are better:

- **Spectral radius decrease.** We examine the extend of the decrease of the spectral radius of the Hazard matrix \(\mathcal{F}\) and, hence, the decrease of the bound of the max influence as described in Proposition 24.4.

- **Expected influence decrease.** We compare the performance of policies in terms of Problem 24.1. To this end, for each Hazard matrix \(\mathcal{F}\), the influence is computed as the average number of infected nodes at the end of more than 1000 runs of the independent cascade CTIC while applying that specific Hazard matrix \(\mathcal{F}\). Each time a single initial influencer is selected by the influence maximization algorithm Pruned Monte Carlo [40] by generating 1000 vertex-weighted directed acyclic graphs (DAGs).

In the empirical study, we focus on the scenario where the spectral radius of the original network is approximately one, which is the setting in which decreasing the spectral radius has the most impact.
Comparison of policies on a synthetic network. Comparison of NetShape’s performance against competitors on the synthetic network SBD10ER, which is a composition of 10 Erdös-Rényi clusters (see details in Section 24.8.1). The values used for the trivalency model to generate edge weights are $p \in \{0.1, 0.2, 0.5\}$. The tested budget values are $k \in \{5, 10, 20, 50, 100\}$. (A) The structure of the generated nonsymmetric, block-diagonal adjacency matrix (here plotted as a binary matrix); (B) Spectral radius $\rho_H(\mathcal{F})$ versus budget $k$; (C) Influence: the expected proportion of infected nodes $\frac{\sigma}{\mathcal{N}}$ versus $k$. Lower values are better.

on the upper bounds in Proposition 24.4 and [12]. We believe that this intermediate regime is the most meaningful and interesting in order to test the different algorithms.

24.8.2 RESULTS
The results on the synthetic network are shown in Fig. 24.3 and those on the three real network datasets in subfigures of Fig. 24.4. The subfigures correspond to the two evaluation measures that we use for a wide range of budget size $k$ in proportion to the number of nodes of that network.
First, we should note that the influence and spectral radius measures correlate generally well across all reported experiments; they present similar decrease w.r.t. budget increase and hence “agree” in the order of effectiveness of each policy when examined individually. As expected, all policies perform more comparably when very few or too many resources are available. In the former case, the very “central” nodes are highly prioritized by all methods while in the latter the significance of node selection diminishes. Even simple approaches perform well in all but Gnutella network where we get the most interesting results. NetShape achieves a sharp drop of the spectral radius early (i.e., for small budget $k$) in Gnutella and Epinions networks, which drives a large influence reduction. With regards to influence minimization, the difference to competitors is bigger, though, in Gnutella which is the most sparse and has the smallest strongly connected component (see Table 24.2). In Facebook, the reduction of the spectral radius is slower and seems less closely related with the influence, in the sense that the upper bound that we optimize is probably less tight to the behavior of the process.

Overall, the performance of the proposed NetShape algorithm is mostly as good or superior to that of the competitors, achieving up to a 50% decrease of the influence on the Gnutella network compared to its best competitor. Similar findings can be claimed for the experiments on the synthetic network SBD10ER.
24.9 CONCLUSION

The future of the diffusion networks field is full of interesting problems and potential applications. It will continue to enrich our understanding of diffusive phenomena and, at a second level, is expected to also change how information is circulated in online social networks.

The subject of this chapter was first to analyze the way information diffusion takes place in modern large-scale online social networks and the challenges regarding the control of certain types of undesired diffusion such as rumors, fake news, and others. We have presented an overview of the complex context in which these information-related diffusive phenomena appear and how individuals participate in the process acting as users of online social platforms.

To present the background of related problems, we went through various approaches for modeling information cascades, including the early used virus models and the more recent independent cascades model. Specifically for the latter model, we spoke about its large-scale dynamics and how that relates to the network properties, the existence of a threshold value that defines the point of transition between subcritical and supercritical behavior, and the connection of that threshold value to the spectral radius of the Hazard matrix of the network.

Subsequently, we discussed a framework that we proposed recently for spectral activity shaping under the Continuous-Time Independent Cascades Model [13] that allows the administrator for local control actions by allocating targeted resources, which can alter locally the spread of the process. The activity shaping is achieved via the optimization of the spectral radius of the Hazard matrix, which enjoys a simple convex relaxation when used to minimize the influence of the cascade. In addition, by reframing a number of use cases, we explained that the proposed framework is general and includes tasks such as partial quarantine that acts on edges and partial node immunization that acts on nodes. Notably, this generic framework can describe complex strategies that may use several immunization options by deploying simultaneously resources of different types (removal of edges, nodes, partial immunization, etc.). Specifically for the influence minimization that is the one directly related to rumor spreading control, we presented the NetShape method, which was compared favorably to baseline and a state-of-the-art method on real benchmark network datasets.

Among the interesting and challenging future work directions, on the same line to the presented framework, there can be the introduction of an “aging” feature to each piece of information that would model its loss of relevance and attraction through time, and the theoretical study and experimental validation of the maximization counterpart of Netshape method.
